Declaration of Originality

I, Kapil Khurana, with SR No. 04-04-00-10-42-18-1-16205 hereby declare that the material presented in the thesis titled

Unmasking Hidden SQL Queries

represents original work carried out by me in the Department of Computer Science and Automation at Indian Institute of Science during the years 2018-2020.

With my signature, I certify that:

- I have not manipulated any of the data or results.
- I have not committed any plagiarism of intellectual property. I have clearly indicated and referenced the contributions of others.
- I have explicitly acknowledged all collaborative research and discussions.
- I have understood that any false claim will result in severe disciplinary action.
- I have understood that the work may be screened for any form of academic misconduct.

Date: Student Signature

In my capacity as supervisor of the above-mentioned work, I certify that the above statements are true to the best of my knowledge, and I have carried out due diligence to ensure the originality of the report.

Advisor Name: Prof. Jayant R. Haritsa Advisor Signature

DEDICATED TO

My Parents

Mrs. Versha Khurana and the late Mr. Omprakash Khurana;

For their endless love, support and encouragement
Acknowledgements

I would like to express my sincere gratitude to my project advisor, Prof. Jayant R. Haritsa for giving me an opportunity to work on this project with him. I am thankful to him for his valuable guidance and continuous support at each and every step. When the going gets tough, the tough get going. That is the kind of spirit he has always worked with and imparted to me.

I would also like to thank the Department of Computer Science and Automation and Indian Institute of Science for providing excellent study environment and research facilities. The learning experience has been really great here. I would like to thank all IISc staff for the role each of them played throughout my journey at IISc.

I would like to thank my lab mates for their valuable inputs and constructive criticism and my friends for supporting me during critical times. Finally, I would like to thank my parents who has always supported me indefinitely.
Abstract

We investigate here the query reverse-engineering problem of unmasking SQL queries hidden within database applications, a problem with use-cases ranging from legacy code to server security. As a first step in addressing this challenge, we present UNMASQUE, an extraction algorithm that is capable of identifying a substantive class of complex hidden queries. A special feature of our design is that the extraction is non-invasive w.r.t. the application, examining only the results obtained from its executions on databases derived with a combination of data mutation and data generation techniques.

Further, potent optimizations, such as database size reduction to a few rows, are incorporated to minimize the extraction overheads. A detailed evaluation over benchmark databases demonstrates that UNMASQUE is capable of correctly and efficiently extracting a broad spectrum of hidden queries. We also show UNMASQUE’s capability to convert imperative code into equivalent SQL queries for some famous blogging applications.

Chapter 1

Introduction

Over the past decade, query reverse-engineering (QRE) has evinced considerable interest from both the database and programming language communities (e.g. [14, 11, 10, 9, 5, 3, 2, 7, 4, 13]). The generic problem tackled in this stream of work is the following: Given a database instance $D_i$ and a populated result $R_i$, identify a candidate SQL query $Q_c$ such that $Q_c(D_i) = R_i$. The motivation for QRE stems from a variety of use-cases, including: (i) reconstruction of lost queries; (ii) query formulation assistance for naive SQL users; (iii) enhancement of database usability through a slate of instance-equivalent candidate queries; and (iv) explanation for unexpectedly missing tuples in the result.

Impressive progress has been made on addressing the QRE problem, with potent tools such as Talos[11], Regal[10] and Scythe[13] having been developed over the years. Notwithstanding, there are intrinsic challenges underlying the problem framework: First, the choice of candidate query is organically dependent on the specific $(D_i, R_i)$ instance provided by the user, and can vary hugely based on this initial sample. As an extreme case in point, if the result has only a single row, the generated candidates are likely to be trivial queries, although the ideal answer may be an aggregation query. Second, given the inherently exponential search space of alternatives, identifying and selecting among the candidates is not easily amenable to efficient processing. Third, the precise values of filter predicates, as well as advanced SQL constructs (e.g. LIMIT, LIKE, UDFs), are fundamentally impossible to deduce since the candidate query is constructed solely from the instance.

In this report, we consider a variant of the QRE problem, wherein a ground-truth query is additionally available, but in a hidden form that is not easily accessible. For example, the original query may be explicitly hidden in a black-box application executable. Moreover, encryption or obfuscation may have been additionally incorporated to further protect the application logic. An alternative scenario is that the application is visible but effectively opaque because it is
comprised of hard-to-comprehend SQL (such as those arising from machine-generated object-relational mappings), or poorly documented imperative code that is not easily decipherable. Such “hidden-executable” situations could arise in the context of legacy code, where the original source has been lost or misplaced over time (prominent instances of such losses are recounted in [22]), or when third-party proprietary tools are part of the workflow, or if the software has been inherited from external developers.

Formally, we introduce the hidden-query extraction (HQE) variant of QRE as follows: Given a black-box application $\mathcal{A}$ containing a hidden SQL query $\mathcal{Q}_H$, and a database instance $\mathcal{D}_i$ on which $\mathcal{Q}_H$ produces a populated result $\mathcal{R}_i$, unmask $\mathcal{Q}_H$ to reveal the original query.

We leverage the presence of the hidden ground-truth to deliver a variety of advantages:

- The outcome now becomes independent of the initial $(\mathcal{D}_i, \mathcal{R}_i)$ instance.
- Since the application can be invoked repeatedly on different databases, efficient and focused mechanisms can be designed to precisely identify the hidden query.
- It allows for capturing difficult SQL constructs (we show here how LIKE, LIMIT, HAVING and scalar UDFs can be extracted).
- As a collateral benefit, the unmasked query can serve as a definitive seed input to database usability tools like Talos[11] which create an array of instance-equivalent queries.
- New use-cases become feasible – for instance, a security agency may wish to ascertain offline the real intent of encrypted queries that were refused entry due to concerns about their origins.

At first glance it may appear that the existing QRE techniques could be used to provide a seed query for HQE, followed by refinements to precisely identify the hidden query. However, as explained later, this is not a viable approach, forcing us to design the extraction procedures from scratch. Our experience in this effort is that HQE proves to be a challenging research problem due to factors such as (a) acute dependencies between the various clauses of the hidden query, (b) possibility of schematic renaming, (c) result compression due to aggregation functions, and (d) presence of UDFs.
1.1 UNMASQUE Algorithm

We take a first step towards addressing the HQE problem here by presenting UNMASQUE
an algorithm that uses a judicious combination of database mutation and synthetic database generation to identify the hidden query $Q_H$. The extraction is completely non-invasive wrt the application code, examining only the results obtained from its executions on carefully constructed databases. As a result, platform-independence is achieved wrt the underlying database engine.

Currently, UNMASQUE is capable of extracting a substantive class of SPJGHAOL queries. As an exemplar, consider $Q_H$ in Figure 1.1a, which encrypts TPC-H [25] query Q3 in a stored procedure, and features most of these clauses. Our extracted equivalent, $Q_E$, is shown in Figure 1.1b, clearly capturing all semantic aspects of the original query, including the scalar revenue UDF. Only syntactic differences, such as a different grouping column order, remain in the extraction.

As a reference point, the candidate query produced by Regal+[10] for this scenario is shown in Figure 1.1c. While the query tables and joins are detected correctly, there are significant discrepancies in the filters, grouping columns and aggregation functions. Moreover, the query is produced after removing limit, order and UDF clauses and converting character and date type columns to integers to suite their environment. Finally, producing even this limited outcome took considerable time and resources.

1.2 Extraction Workflow

UNMASQUE operates according to the pipeline shown in Figure 1.2, where it unmasks the hidden query elements in a structured manner. It starts with the FROM clause, continues on to the JOIN and FILTER predicates, follows up with the PROJECTION and GROUP BY+AGGREGATION
columns, and concludes with the ORDER BY and LIMIT functions (as explained in Section 6.2, a different pipeline structure is required to extract HAVING clause). The initial elements are extracted using database mutation strategies, whereas the subsequent ones are extracted leveraging database generation techniques. Further, while some of the elements are relatively easy to extract (e.g. FROM), there are others (e.g. GROUP BY) that require carefully crafted methods for unambiguous identification. The final component in the pipeline is the QUERY ASSEMBLER which puts together the different elements of \( Q_E \) and performs canonification to ensure a standard output format.

### 1.3 Extraction Efficiency

To cater to extraction efficiency concerns, UNMASQUE incorporates a variety of optimizations. In particular, it solves a conceptual problem of independent interest: Given a database instance \( D \) on which a hidden query \( Q_H \) produces a populated result \( R \), identify the smallest subset \( D_{min} \) of \( D \) such that the result of \( Q_H \) continues to be populated.

At first glance, it may appear that \( D_{min} \) can be easily obtained using well-established provenance techniques (e.g. [6]). However, due to the hidden nature of \( Q_H \), these approaches are no longer viable. Therefore, we design alternative strategies based on a combination of sampling and recursive database partitioning to achieve the minimization objective.

The database minimization is applied immediately after the FROM clause has been identified, as shown in Figure 1.2. And the reduction is always to the extent that the subsequent SPJ extraction is carried out on miniscule databases containing just a handful of rows. In an analogous fashion, the synthetic databases created for the GAOL extraction are also carefully designed to be very thinly populated. Overall, these reductions make the post-minimization
processing to be essentially independent of database size.

1.4 Performance Evaluation

We have evaluated UNMASQUE’s behavior on a suite of complex decision-support queries, and on imperative code sourced from blogging tools. The performance results of these experiments, conducted on a vanilla PostgreSQL [20] platform, indicate that UNMASQUE precisely identifies the hidden queries in our workloads in a timely manner. As a case in point, the extraction of the example Q3 on a 100 GB TPC-H database was completed within 10 minutes. This performance is especially attractive considering that a native execution of Q3 takes around 5 minutes on the same platform.

1.5 Organization

The rest of the report is organized as follows: In Chapter 2, a precise description of the HQE problem is provided, along with the notations. The following chapters – Chapter 3 and 4 – present the components of the UNMASQUE pipeline, which progressively reveal different facets of the hidden query. The experimental framework and performance results are reported in Chapter 5. Extraction of the HAVING clause and other extensions are discussed in Chapter 6. Chapter 7 summarizes some theoretical results about HQE. Finally, our conclusions and future research avenues are summarized in Chapter 8.
Chapter 2

Problem Framework

We assume that an application executable object file is provided, which contains either a single SQL query or imperative logic that can be expressed in a single query. If there are multiple queries in the application, we assume that each of them is invoked with a separate function call, and not batched together, reducing to the single query scenario. This assumption is consistent with open source projects such as Wilos [27], which contain code segments wherein each function implements the logic of a single relational query.

If the hidden SQL query is present as-is in the executable, it can be trivially extracted using standard string extraction tools (e.g. Strings [17]). However, if there has been post-processing, such as encryption or obfuscation, for protecting the application logic, this option is not feasible. An alternative strategy is to re-engineer the query from the execution plan at the database engine. However, this knowledge is also often not accessible – for instance, the SQL Shield tool[23] blocks out plan visibility in addition to obfuscating the query. Finally, if the query has been expressed in imperative code, then neither approach is feasible for extraction.

Moving on to the database contents, there is no inherent restriction on column data types, but we assume for simplicity, the common numeric (int, bigint and float with fixed precision), character (char, varchar, text), date and boolean types. The database is freely accessible through its API, supporting all standard DML and DDL operations, including creation of a test silo in the database for extraction purposes.

2.1 Extractable Query Class

The QRE literature has primarily focused on constructing generic SPJGA queries that do not feature non-equi-joins, nesting, disjunctions or UDFs. We share some of the restrictions but have been able to extend the query extraction scope to include HOL constructs, as well as
simple scalar UDFs. Further, we expect join graph to be a subgraph of schema graph. There are additional mild constraints on some of the constructs – for instance, the LIMIT value must be at least 3, there are no filters on key attributes – and they are mentioned in the relevant locations in the following chapters. We hereafter refer to this class of supported queries as *Extractable Query Class* (EQC). Our subsequent description of UNMASQUE on EQC uses the sample TPCH Query 3 of the Introduction (Figure 1.1a) as the running example.

For ease of exposition and due to space limitations, we initially present UNMASQUE for SPJGAOL queries, and defer the HAVING clause to Section 6.2. Further, we assume a slightly simplified framework in the subsequent description – for instance, that all keys are positive integer values – the extensions to the generic cases are provided at the end.

The notations used in our description of the extraction pipeline are summarized in Table 2.1. To highlight its black-box nature, the application executable is denoted by $\mathcal{F}$, while $\overrightarrow{O}_E$ has a vector symbol to indicate that the ordering columns form a sequence.

### 2.2 Overview of the Extraction Approach

To set up the extraction process, we begin by creating a silo in the database that has the same table schema as the original user database. Subsequently, all referential integrity constraints are dropped from the silo tables, since the extraction process requires the ability to construct alternative database scenarios that may not be compatible with the existing schema. We then create the following template representation for the to-be extracted query $Q_E$:

$$\text{Select} \ (P_E, A_E) \ \text{From} \ T_E \ \text{Where} \ J_E \land F_E$$

$$\text{Group By} \ G_E \ \text{Order By} \ \overrightarrow{O}_E \ \text{Limit} \ l_E;$$

and sequentially identify each of the constituent elements, as per the pipeline shown in Figure 1.2.

The initial segment of the pipeline is based on mutations of the original/reduced database
and is responsible for handling the SPJ features of the query which deliver the raw query results. The modules in this segment require targeted changes to a specific table or column while keeping the rest of the database intact.

In contrast, the second pipeline segment is based on the generation of carefully-crafted synthetic databases. It caters to the GAOL query clauses, which are based on manipulation of the raw results. The modules in this segment require generation of new data for all the query-related tables under various row-cardinality and column-value constraints. We deliberately depart from the mutation approach here since these constraints may not be satisfied by the original database instance.

We hereafter refer to these two segments as the Mutation Pipeline and the Generation Pipeline, respectively, and present them in detail in the following chapters.
Chapter 3

Mutation Pipeline

The SPJ core of the query, corresponding to the FROM ($T_E$), WHERE ($F_E, J_E$) and SELECT ($P_E$) clauses, is extracted in the Mutation Pipeline segment of UNMASQUE. Aggregation columns in the SELECT clause are only identified as projections here, and subsequently refined to aggregations in Generation Pipeline.

3.1 From Clause

To identify whether a base table $t$ is present in $Q_H$, the following elementary procedure is applied: First, $t$ is temporarily renamed to $temp$. Then, $F$ is executed on this mutated schema and we check whether it throws an error – if yes, $t$ is part of the query; Finally, $temp$ is reverted to its original name $t$.

By doing this check iteratively over all the tables in the schema, $T_E$ is identified. With $Q3$, the procedure results in

$T_E = \{\text{customer, lineitem, orders}\}$.

3.2 Database Minimization

For enterprise database applications, it is likely that $D$ is huge, and therefore repeatedly executing $F$ on this large database during the extraction process may take an impractically long time. To tackle this issue, before embarking on the SPJ extraction, we attempt to minimize the database as far as possible while maintaining a populated result. Specifically, we address the following row-minimality problem:

Given a database instance $D$ and an executable $F$ producing a populated result on $D$, derive a reduced database instance $D_{\text{min}}$ from $D$ such that removing any row of any table in $T_E$ results in an empty result.
With this definition of $D_{\min}$, we can state the following strong observation for $EQC^{-H}$ (EQC without HAVING):

**Lemma 3.1:** For the $EQC^{-H}$, there always exists a $D_{\min}$ wherein each table in $T_E$ contains only a single row.

**Proof:** Firstly, since the final result is known to be populated, the intermediate result obtained after the evaluation of the SPJ core of the query is also guaranteed to be non-empty. This is because the subsequent GAOL elements only perform computations on the intermediate result but do not add to it. Now, if we consider the provenance for each row $r_i$ in the intermediate result, there will be exactly one row as input from each table in $T_E$ because: (i) if there is no row from table $t$, $r_i$ cannot be derived because the inner equi-join (as assumed for the query class EQC) with table $t$ will result in an empty result; (ii) if there are $k : (k > 1)$ rows from $t$, $(k - 1)$ rows either do not satisfy one or more join/filter predicates and can therefore be removed from the input, or they will produce a result of more than one row since there is only a single instance of $t$ in the query. In essence, a single-row $R$ can be traced back to a single-row per table in $D_{\min}$. □

We hereafter refer to this single-row $D_{\min}$ as $D^1$ – the reduction process to identify this database is explained next.

**Reducing $D$ to $D^1$**

At first glance, it might appear trivial to identify a $D^1$ – simply pick any row from the $R$ obtained on $D$ and compute its provenance using the well-established techniques in the literature (e.g. [6]) – the identified source rows from $T_E$ constitute the single-row $D^1$. However, these tuple provenance techniques in the literature are predicated on prior knowledge of the query. This makes them unviable for identifying $D^1$ in our case where the query is hidden. Therefore, we implement the following iterative-reduction process instead: Pick a table $t$ from $T_E$ that contains more than one row, and divide it roughly into two halves. Run $F$ on the first half, and if the result is populated, retain only this first half. Otherwise, retain only the second half, which must, by definition, have at least one result-generating row (due to Lemma 3.1). When eventually all the tables in $T_E$ have been reduced to a single row by this process, we have achieved $D^1$.

In principle, the tables in $T_E$ can be progressively halved in any order. However, note that after each halving, $F$ is executed to determine which half to retain, and therefore we would like to minimize the time taken by these executions. Accordingly, we choose a policy of always halving the currently largest table in the set. This is because this policy can be shown to
require, in expectation, the least amount of data processing to reach the $D^1$ target.

To make the above concrete, a sample $D^1$ for Q3 (created from an initial 100 GB instance) is shown in Figure 3.1.

### 3.3 Join Predicates

To extract the join predicates $J_E$ of $Q_H$, we start with $SG$, the original schema graph of the database. Note that, the nodes in $SG$ are key columns (and not tables which is usually the case with the term, schema graph) and each edge $(u,v)$ denotes an equi-join predicate $u = v$. From $SG$, we create an (undirected) induced subgraph whose vertices are the key columns in $T_E$, and edges are the possible join edges between these columns. In the case of composite keys, each column within the key is treated as a separate node.

After that, each connected component in the subgraph is converted to a corresponding cycle graph, hereafter referred to as a cycle, with the same set of vertices. Note that the elementary graph with two nodes and and an edge connecting them is also considered to be a cycle. The motivation for this graph conversion step is the following: Checking for the presence of a connected component in the query join graph $JG_E$, is equivalent to checking the presence of the corresponding cycle. Therefore the collection of all the cycles put together is referred to as candidate join-graph, or $CJG_E$.

We now individually check for the presence of each $CJG_E$ cycle in $JG_E$, using the iterative
procedure shown in Algorithm 1. The check is done in the following three steps: (i) Using
the Cut procedure, remove a pair of edges from a candidate cycle CC; this partitions CC into
two connected components; these new components are converted into cycles (C₁ and C₂) by
adding the missing edge; (ii) Negate in 𝒟¹ all the values in the columns corresponding to the
vertices in C₁, using the Negate procedure; (iii) Run 𝐹 on this mutated database – if the result
is empty, we conclude the edges are present in 𝐽𝑮𝑬 and the edges are returned to the parent
cycle CC; otherwise, C₁ and C₂ are included as fresh candidates in 𝐶 𝐽𝑮𝑬. If a candidate cycle
has reduced to a single edge, then the check is carried out only with the Negation step using
one of the two vertices.

In the above procedure, the motivation behind removing a pair of edges is the observation
that for 𝐽𝑮𝑬 to not contain a cycle CC, at least two edges of CC should be absent from
𝐽𝑮𝑬. The reason is that, in the above context, if an edge is removed from a cycle, the resultant
graph is still equivalent to the cycle due to transitivity property of inner-equi join over columns.
Further, the algorithm is bound to terminate because in each iteration, a cycle is either removed
or partitioned into smaller cycles.

With regard to Q3, 𝐶 𝐽𝑮𝑬 contains only two connected components – specifically, (l_orderkey, o_orderkey)
and (o_custkey, c_custkey). Each component has a single edge that returns true when checked
for presence by Algorithm 1. So, in this case, 𝐽𝑮𝑬 ≡ 𝐶 𝐽𝑮 𝒆. In the final step, each edge in
𝐽𝑮𝑬 is converted into a predicate in 𝐽. Therefore, for Q3, the join predicates turn out to be:

\[ 𝐽 = \{ l_{\text{orderkey}} = o_{\text{orderkey}}, o_{\text{custkey}} = c_{\text{custkey}} \}. \]

Lemma 3.2: For a hidden query \( Q_H \in \text{EQC} \), UNMASQUE correctly extracts \( JG_E \), or
equivalently, \( J_E \).

Proof: It is easy see that when there is only one edge in the cycle, it will be correctly
extracted as the output after removing it will be empty iff this edge is present in the join graph.
For the edges that belong to bigger cycles, we prove the claim by contradiction. Consider an
edge \((u, v)\) that belongs to \( JG_E \) but UNMASQUE fails to extract it (i.e. a false negative). This
implies that when the edge \((u, v)\) is removed by value negation (with any other edge) the result
continues to be populated. This is not possible if \((u, v) \in JG_E\) as one of the nodes from u and
v is negated.

On the other hand, consider an edge \((u, v) \in C\) that is not part of \( JG_E \) but UNMASQUE
extracts it (i.e. a false positive). This implies that when the edge \((u, v)\) is explicitly removed
along with any other edge \((x, y)\) by value negation, the result becomes empty. As there is no
other filter on key attributes and \((u, v) \notin JG_E\), every other edge in \( C \) must belong to the join
graph. Now due to inner-equi joins \((u, v)\) also belongs to the join graph as it can be inferred
by other edges of cycle $C$, a contradiction.

3.4 Filter Predicates

We start by assuming that all columns in $C_E$ (set of columns in $T_E$) are potential candidates for the filter predicates $F_E$ in $Q_H$. Each of them is then checked in turn with the following procedure: First, we evaluate whether there is a nullity predicate on the column. If an IS NULL predicate is not present, we investigate whether there is an arithmetic predicate, and if yes, the filter value(s) for the predicate are identified.

It is relatively easy to check for nullity predicates and, more generally, predicates on any data types with small finite domains (e.g. Boolean), by simply mutating the attribute with each possible value in its domain and observing the result – empty or populated – of running $F$ on these mutations. The procedure for general numeric and textual attributes is, however, more involved, as explained below.
<table>

<td>Find $l$ and $r$</td>
</tr>
</tbody>
</table>

Table 3.1: Filter Predicate Cases

### 3.4.1 Numeric Predicates

For ease of presentation, we start by explaining the process for integer columns. Let $[i_{min}, i_{max}]$ be the value range of column $A$’s integer domain, and assume a range predicate $l \leq A \leq r$, where $l$ and $r$ need to be identified. Note that all the comparison operators ($=, <, >, \leq, \geq, between$) can be represented in this generic format – for example, $A < 25$ can be written as $i_{min} \leq A \leq 24$.

To check for presence of a filter predicate on column $A$, we first create a $D_{mut}^1$ instance by replacing the value of $A$ with $i_{min}$ in $D^1$, then run $F$ and get the result – call it $R_1$. We get another result – call it $R_2$ – by applying the same process with $i_{max}$. Now, the existence of a filter predicate is determined based on one of the four disjoint cases shown in Table 3.1.

If the match is with Case 2 (resp. 3), we use a binary-search-based approach over $(i_{min}, a]$ (resp. $[a, i_{max}]$), to identify the specific value of $l$ (resp. $r$), where $a$ is the value of column $A$ that is present in $D^1$. After this search completes, the associated predicate is added to $F_E$.

Finally, Case 4 is a combination of Cases 2 and 3, and can therefore be handled in a similar manner.

We can easily extend the integer approach to float data types with fixed precision, by first identifying the integral bounds with the above procedure and then executing a second binary search to identify the fractional bounds. For example, with $l_i$ and $r_i$ as the integral bounds identified in the first step, and assuming a precision of 2, we search $l$ in $((l_i - 1).00, l_i.00]$ and $r$ in $[r_i.00, r_i.99)$ in the second step.

### 3.4.2 Date Columns

Extracting predicates on date columns is identical to that of integers, with the minimum and maximum expressible dates in the database engine serving as the initial range, and days as the difference unit. For example, after identifying filter of type $A \leq r$ on $o_{orderdate}$, we apply binary search strategy in range $[‘1994-12-31’, r]$ (assuming ‘1994-12-31’ is the value of $o_{orderdate}$ in $D^1$) and $r$ is the greatest allowed date value in the database engine (for PostgreSQL, $r = 5874897AD$). Note that the same strategy can be applied to other datetime type columns with the corresponding change in the resolution of values.
3.4.3 Boolean Columns

With a single row, a boolean column can have only one of True or False values. Therefore, to identify a filter on boolean column \( t.A \), we create a \( D_{mut}^1 \) by replacing its value in \( D^1 \) with True (resp. False) if the current value in \( D^1 \) is False (resp. True) and get the result. If the result is empty, add “\( A = False \)” (resp. “\( A = True \)” to \( F_E \).

3.4.4 Textual Predicates

The extraction procedure for character columns is significantly more complex because (a) strings can be of variable length, and (b) the filters may contain wildcard characters (‘\_’ and ‘%’). To first check for the existence of a filter predicate, we create two different \( D_{mut}^1 \) instances by replacing the value of \( A \) initially with an empty string and then with a single character string—say “a”. \( F \) is invoked on both these instances, and we conclude that a filter predicate is in operation iff the result is empty in one or both cases. To prove the if part, it is easy to see that if the result is empty in either of the cases, there must be some filter criteria on \( A \). For the only if part, the result will be populated for both cases in only one extreme scenario—\( A \) like ‘%’, which is equivalent to no filter on \( A \).

Upon confirming the existence of a filter predicate on \( A \), we extract the specific predicate in two steps. Before getting into the details, we define a term called Minimal Qualifying String (MQS). Given a character/string expression \( val \), its MQS is the string obtained by removing all occurrences of ‘%’ from \( val \). For example, “UP_” is the MQS for “%UP_%”. Note that each character of MQS, with the exception of wildcard ‘\_’, must be present in the data string to satisfy the filter predicate. With this notation, the first step is to identify MQS using the actual value of \( A \) in \( D^1 \), denoted as the representative string, or \( rep_str \). The formal procedure to identify MQS is detailed in Algorithm 2. The basic idea here is to loop through all the characters of \( rep_str \) and determine whether it is present as an intrinsic character of the MQS or invoked through the wildcards (‘\_’ or ‘%’). This distinction is achieved by replacing, in turn, each character of \( rep_str \) in \( D^1 \) with some other character, executing \( F \) on this mutated database, and checking whether the result is empty—if yes, the replaced character is part of MQS; if no, this character was invoked through wildcards. In this case, further action is taken to identify the correct wildcard character. Note that in case the character in \( rep_str \) occurs more than once without any intrinsic character in between, and only one of them is part of MQS, our procedure puts the rightmost character in MQS.
Lemma 3.3: For a query in EQC, Algorithm 2 correctly identifies MQS for a filter predicate on character attribute.

Proof: The correctness of the algorithm 2 can be established using contradiction for each of the possible failed cases. For example, let us say a character ‘a’ belonged to MQS but the procedure fails to identify it. This means that after removing ‘a’ from rep_str, the result is still non-empty (the filter condition was satisfied). This is possible when ‘a’ occurs more than once in rep_str and there is at least one occurrence which is part of the replacement for wildcard ‘%’. However, the procedure will keep removing ‘a’ until there is no occurrence left which is part of replacement for wildcard ‘%’. After that, removing ‘a’ will lead the corresponding filter predicate to fail. If this is not the case, ‘a’ is not present in the MQS, a contradiction. Similarly, the correctness for other cases can be proved.

Algorithm 2: Identifying MQS

1. **Input:** Column A, rep_str, D
2. **itr** = 0; MQS = ""
3. while **itr** < len(rep_str) do
   4.   temp = rep_str
   5.   temp[itr] = c where c ≠ rep_str[itr]
   6.   D
   7.   if F(D
   8.     MQS.append(rep_str[itr+1])
   9.   else
   10.     temp.remove_char_at(itr)
   11.     D
   12.     if F(D
   13.       MQS.append(‘?’); itr++
   14.     else
   15.       rep_str.remove_char_at(itr)
   16.     end
   17. end

After obtaining the MQS, we need to find the locations (if any) in the string where ‘%’ is to be placed to get the actual filter value. This is achieved with the following simple linear procedure: For each pair of consecutive characters in MQS, we insert a random character that
is different from both these characters and replace the current value in column \( A \) with this new string. A populated result for \( \mathcal{F} \) on this mutated database instance indicates the existence of ‘%’ between the two characters. The inserted character is removed after each iteration and we start with the initial MQS for each successive pair of consecutive characters. This makes sure that we correctly identify the locations of ‘%’ without exceeding the character length limit for \( A \). In the specific case of \( Q3 \), the predicate value for \( c_{\text{mktsegment}} \) turns out to be the MQS itself, namely ‘BUILDING’.

Overall, for query \( Q3 \), the following numeric and textual filter predicates are identified by the above procedures:

\[
F_E = \{ \text{o_orderdate} \leq \text{date ‘1995-03-14’} , \text{l_shipdate} \geq \text{date ‘1995-03-16’} , \text{c_mktsegment} = \text{‘BUILDING’} \}
\]

### 3.5 Projections

The identification of projections is rendered tricky since they may appear in a variety of different forms – native columns, renamed columns, aggregation functions on the columns, or UDFs with column variables. To have a unified extraction procedure, we begin by treating each result column as an (unknown) constrained scalar function of one or more database columns. We explain here the procedure for identifying this function, assuming linear dependence on the column variables and at most two columns featuring in the function – the extension to more columns is discussed at last.

Let \( O \) denote the output column, and \( A, B \) the (unknown) database columns that may affect \( O \). Given our assumption of linearity, the function connecting \( A \) and \( B \) to \( O \) can be expressed with the following equation structure:

\[
aA + bB + cAB + d = 0 \tag{3.1}
\]

where \( a, b, c, d \) are constant coefficients. With this framework, the extraction process proceeds, as explained below, in two steps: (i) Dependency List Identification, which identifies the identities of \( A, B \), and (ii) Function Identification, which identifies the values of \( a, b, c, d \).

#### 3.5.1 Dependency List Identification

In this step, for each \( On \), the set of database columns which affect its value is discovered via iterative column exploration and database mutation. Specifically, the value of each database
column in $C_E$ (the set of columns in $T_E$) is mutated in turn to see whether or not it affects the value of $O$. However, a subtle point here is that even in the simplified two-variable scenario, a single pass through all the database columns may not always be sufficient to obtain the complete dependency list of $O$. To make it more concrete, if the value of column $A$ in $D^1$ happen to be $-\frac{b}{c}$, then the entry in column $B$ has no impact on $O$, irrespective of its value. We say that $A$ is a blocking column and $B$ is the blocked column for that database instance. Similarly, if the value of column $B$ in $D^1$ happen to be $-\frac{a}{c}$, then column $A$ is blocked by column $B$. To address such boundary conditions, we perform a second iteration in case the dependency list contains less than two columns after first iteration. However, before the second iteration, the values in all the database columns are changed to new values keeping filter predicates in consideration. Now, if a column $A$ was blocked before by another column $B$, it will no longer be blocked due to the change in the value in column $B$, and hence - it will be identified in the second iteration.

Finally, as a special case, if the output column represents $\text{COUNT}(*)$, its dependency list will be empty.

For $Q3$, the following dependency lists are obtained with the above procedure: $\text{l_orderkey: [l_orderkey]}$, $\text{o_orderdate: [l_orderkey]}$, $\text{o_shippriority: [o_shippriority]}$, and $\text{revenue: [l_extendedprice, l_discount]}$.

### 3.5.2 Function Identification

With reference to Equation 3.1, at this stage we are aware of the identities of $A$ and/or $B$ for each of the output columns, and what remains is to obtain the coefficient values $a, b, c, d$. Since we have a non-homogeneous equation in 4 unknowns, it can be easily solved by creating 4 different $D^1_{mut}$ instances such that the resultant equations are linearly independent. This is achieved by randomly mutating the values of $A$ and $B$, checking whether the new vector $[A, B, AB, 1]$ is linearly independent from the vectors generated so far, and stopping when four such vectors have been found. With regard to $Q3$, the revenue output column depends on $A = l_{\text{extendedprice}}$ and $B = l_{\text{discount}}$. The sample four equations, corresponding to output column revenue, generated in our experiments are as below:

1. $a + 2.b + 2.c + d = -1$ \hspace{2cm} (3.2)
2. $a + 1.b + 2.c + d = 0$ \hspace{2cm} (3.3)
3. $a + 3.b + 6.c + d = -4$ \hspace{2cm} (3.4)
4. $a + 4.b + 4.c + d = -3$ \hspace{2cm} (3.5)
Solving the above system results in coefficient values: $a = 1, b = 0, c = -1, d = 0$, producing the function seen in Q3. For the remaining output columns, which are all dependent on only a single database column, we get the function of the form $aA + d$ with $a = 1, d = 0$ – i.e. a native column.

Thus for query Q3, we obtain:

$$\tilde{P}_E = \{l\_orderkey: l\_orderkey, o\_orderdate: o\_orderdate, o\_shippriority: _shippriority, revenue: l\_extendedprice * (1 - l\_discount) \}.$$  

The reason we show the above set as $\widetilde{P}_E$, and not $P_E$, is that some of these projections are subsequently refined as aggregations ($A_E$) in the Generation Pipeline – for instance, $\text{revenue}$ becomes a $\text{sum}$. We did not have to concern ourselves with these aggregation functions in the current stage because our extraction techniques operated on single-row databases, in which case all aggregation functions are identical with regard to their values.

A closing note regarding the scope of scalar UDFs currently covered in UNMASQUE: Firstly, the above process can be generalized to $m$ column variables in the function if we are able to generate $2^m$ different $D_{mut}$ instances. Secondly, we can handle the CASE switch statements on categorical domains, such as those seen in TPCH Q12. Finally, ancillary functions such as $\text{substring}$, $\text{casting}$, $\text{median}$, etc. can also be extracted.
Chapter 4

Generation Pipeline

The GAOL part of the query, corresponding to the GROUP BY ($G_E$), AGGREGATION ($A_E$), ORDER BY ($O_E$) and LIMIT ($l_E$) clauses, is extracted in the Generation Pipeline segment of UNMASQUE. Here, synthetically generated miniscule databases are used for all the extractions, as described in the remainder of this chapter.

4.1 Group By Columns

For each column $t.A$ in $C_E$ (the set of columns in $T_E$), we generate a database instance $D_{gen}$ and analyze $F(D_{gen})$ for the existence of $t.A$ in $G_E$, the columns in the GROUP BY clause. However, we skip this check for columns with equality filter predicates (as determined in Mutation Pipeline) since their presence or absence in $G_E$ makes no difference to the query output.

Assume for the moment that we have generated a $D_{gen}$ such that the (invisible) intermediate result produced by the SPJ part of $Q_H$ contains 3 rows satisfying the following condition: $t.A$ has a common value in exactly two rows, while all other columns have the same value in all three rows. Now, if the final result contains 2 rows, it means that this grouping is only due to the two different values in $t.A$, making it part of $G_E$. This approach to intermediate result generation is similar to the techniques presented in [8, 12].

Generating $D_{gen}$

We now explain how to produce the desired $D_{gen}$ for checking the $G_E$ membership of a generic column $t.A$. In our description, assigning $(p, q, r, ...)$ to $t.A$ means assigning value $p$ in the first row, $q$ in the second row, $r$ in the third and so on. The database generation is performed differently for the following two disjoint cases related to the presence or absence of $t.A$ in the $JG_E$, the query join graph identified in Mutation Pipeline:
In this case, 3 rows are generated for table \( t \) and only one row in each of the other tables in \( T_E \). For column \( t.A \), any two different values \( p \) and \( q \) that satisfy all associated filter predicates are assigned. If no filter exists, any two values from \( t.A \)'s domain are taken (e.g. \( p = 1 \) and \( q = 2 \) for numeric). After that, we assign \((p, p, q)\) to \( t.A \).

For all other columns in \( t \), such as \( t.X \), a single value \( r \) that satisfies its associated filter predicates (if any) is selected, and \((r, r, r)\) is assigned to \( t.X \). If there is no filter, any value from its domain (e.g. \( r = 1 \) for numeric) is assigned. Finally, if \( t.X \in JG_E \), a fixed value of \( r = 1 \) is assigned (consistent with the assumption of integral keys). A similar assignment policy is used for all columns belonging to the remaining tables in \( T_E \).

An example \( D_{gen} \) for checking the presence of \( o\_orderdate \) in \( G_E \) is shown in Figure 4.1. Here, the ORDERS table features 3 rows with \( p = '1995-03-13' \) and \( q = '1995-03-14' \), while the remaining tables, LINEITEM and CUSTOMER, have a single row apiece. (We hasten to add that these intermediate results are shown just for illustrative purposes, but remain invisible to the UNMASQUE tool in its extraction process.)

\[ \text{(Case 1)} \quad t.A \notin JG_E \]

In this case, 3 rows are generated for table \( t \) and only one row in each of the other tables in \( T_E \). The assignment of values in the tables is similar to Case 1 with the following modifications: (i) \( p \) and \( q \) are assigned fixed values of 1 and 2, (ii) Each columns \( t'.B \) having a path to \( t.A \) in \( JG_E \), is assigned fixed values \((1, 2)\) and all other columns of the corresponding table \( t' \) are assigned values just like for \( t'.X \) in Case 1, except that the assignment is now duplicated across the two rows.

An example \( D_{gen} \) for checking the presence of \( l\_orderkey \) in \( G_E \) is shown in Figure 4.2. Here, there are 3 rows for LINEITEM, 2 rows for ORDERS and 1 row for CUSTOMER.

It is straightforward to see by inspection that, with our EQC restriction to key-based equi-
joins, the above data generation procedure results in ensuring the desired conditions for the intermediate SPJ result. Namely, that it will contain 3 rows with all columns having the same value across these rows except for the attribute under test which has two values across these rows.

It is possible that after all attributes have been processed in the above manner, \( G_E \) turns out to be empty. In this case, we create a \( D_{gen} \) with each table having two rows, each column in \( JG_E \) assigned fixed values \( (1, 2) \), and any two different values to all other columns while satisfying all filter predicates. Then, \( F \) is run on this \( D_{gen} \), and if the result contains just one row, we can conclude that the query has an ungrouped aggregation.

Overall, the above procedure produces for Q3:
\[
G_E = \{l_{\text{orderkey}}, o_{\text{shippriority}}, o_{\text{orderdate}}\}.
\]

4.2 Aggregation Functions

We explain here the procedure for identifying aggregations (\( \min() \), \( \max() \), \( \text{count}() \), \( \text{sum}() \), \( \text{avg}() \)) – due to space limitations, we restrict our attention to numeric attributes. However, similar methods can be used for textual/date attributes as well. Further, for ease of presentation, we assume that there is no \textit{distinct} aggregation – such specialized cases are handled at last.

As described in 3.5, the Projections Extractor extracts each output column as a function of the database columns in its dependency list. For each columns \( O \) in \( \widetilde{P}_E \), the aggregation identification goes as follows: Let \( O = \text{agg}(f_o(A_1, ..., A_n)) \) where \( \text{agg} \) corresponds to the aggregation and \( f_o \) corresponds to the function identified in Section 3.5. Now our goal is to generate a database \( D_{gen} \) such that the final result cardinality is 1, and each of the five possible aggregation functions on \( f_o \) results in a unique value, thereby allowing for correct identification of
the specific aggregation. We call this the “target result”.

Since we want to be able to distinguish between $\text{min}()$ and $\text{max}()$, we need at least two different values in the input database columns. Further, to ensure unique values for the various aggregations in the final output, we do the following: Consider a pair of input arguments $(a_1, ..., a_i, ..., a_n)$ and $(a_1, ..., a'_i, ..., a_n)$ such that $f_o(a_1, ..., a_i, ..., a_n) = o_1$ and $f_o(a_1, ..., a'_i, ..., a_n) = o_2$, with $o_1 \neq 0, o_1 \neq o_2$. Note that the two arguments differ only in $a_i$ and $a'_i$. Now assume we have generated a database $D_{\text{gen}}$ such that there are $k + 1$ rows in the (invisible) intermediate result produced by the SPJ part of the query with value $f_o = o_1$ in $k$ rows and $f_o = o_2$ in the remaining row. Further, that $k$ satisfies the following constraint:

$$k \notin \left\{0, o_1 - 1, o_2 - 1, \frac{o_1 - o_2}{o_1}, \frac{1 - o_2}{o_1 - 1}, \frac{(o_2 - 2) \pm \sqrt{(o_1 - 2)^2 - 4(1 - o_2)}}{2}\right\} \quad (4.1)$$

These constraints on $k$ have been derived by computing pairwise equivalences of the five aggregation functions, and forbidding all the $k$ values that result in any equality across functions. Now, additionally if we ensure that the $G_E$ attributes are assigned common values in all the rows, the result of $F$ will be the target result.

The reason that the target result is produced is (i) the result cardinality is 1 since there is a common set of values for the $G_E$ attributes, and (ii) the constraints on $k$ ensure unique aggregated output of all the aggregations for $O$. (As a special case, if $f_o$ is a constant function or a function of only the columns in $G_E$, we are forced to have $a_i = a'_i$ and hence, $o_1 = o_2 = c$. Here, the $k$ constraint reduces to $k \notin \{0, c - 1\}$ and since multiple aggregations on $f_o$ will be equivalent (e.g. $\text{min}()$, $\text{max}()$, $\text{avg}()$), any can be taken as the final choice.

**Generating $D_{\text{gen}}$**

Firstly, we choose the $i^{th}$ argument $A_i$ to be a column that is not in $G_E$. If choosing such $A_i$ is not possible, then as mentioned above, $a_i = a'_i$ and any argument column can be chosen as $A_i$. After that, the data generation process to obtain the above intermediate result for output column $O = \text{agg}(f_o(A_1, ..., A_n))$ is similar to the $D_{\text{gen}}$ generation of GROUP BY (explained in section 4.1), with the following changes:

- $k + 1$ rows are generated for table $t$ where $A_i \in t$, with $t.A_i$ assigned value $a_i$ in $k$ rows and value $a'_i$ in the remaining row.
- With respect to Case 2 ($t.A_i \in JG_E$) in section 4.1, the assignments of fixed values 1, 2 are replaced with values $a_i, a'_i$. 

23
We can either use any two of the arguments that were used to identify dependency list for \( f_o \) in Section 3.5 as \((a_1, ..., a_i, ..., a_n)\) and \((a_1, ..., a'_i, ..., a_n)\) since they are known assignments that satisfy the required conditions, or generate a new set of arguments. Further, the least positive integer satisfying Equation 4.1 is chosen as \( k \). A sample \( D_{gen} \) to check for aggregation on \( l_{\text{extendedprice}} \times (1 - l_{\text{discount}}) \) is shown in Figure 4.3. Here we set \((l_{\text{extendedprice}}, l_{\text{discount}})\) as \(<(3, 0), (4, 0)>\) and \( k = 1 \) is feasible.

After getting \( D_{gen} \), we run \( \mathcal{F} \) and the aggregation is identified by matching the result column value (corresponding to \( O \)) with the corresponding unique values for the five aggregations. The identified aggregation along with the mapping to the corresponding result column is added to \( A_E \).

At last, entries corresponding to all the aggregated columns are removed from \( \widetilde{P}_E \) and inserted in \( A_E \). Further, if there remains an unmapped output column in \( \widetilde{P}_E \), it is removed and \( \text{count}(\ast) \) is added to \( A_E \). Whatever remains in \( \widetilde{P}_E \) now constitutes the native (i.e. unaggregated) \( P_E \).

With the above procedure, we finally obtain for Q3:

\[
A_E = \{\text{revenue:sum}(l_{\text{extendedprice}} \times (1 - l_{\text{discount}}))\}
\]

\[
P_E = \{l_{\text{orderkey}}:l_{\text{orderkey}}, o_{\text{orderdate}}:o_{\text{orderdate}}, o_{\text{shippriority}}:o_{\text{shippriority}}\}
\]

**Extension to DISTINCT keyword**

In case the aggregation can be present with \textit{DISTINCT} keyword as well, the following cases may happen as a result of identifying aggregation (without \textit{distinct}) using above method:

**Case1 - min() or max() aggregation is identified:** In such a case, no action is required as \textit{min()} or \textit{max()} produces exactly same result with/without unique.
Case 2 - No aggregation is identified: In such a case, the aggregation on $f_o$ is one of $\sum(\text{DISTINCT } f_o)$, $\text{avg}(\text{DISTINCT } f_o)$ or $\text{count}(\text{DISTINCT } f_o)$. To identify the correct aggregation, we generate the $D_{\text{gen}}$ such that $f_o$ having values $(o_1, o_2)$ such that $o_1 \neq o_2$ and $(o_1 + o_2) \notin \{2, 4\}$ to get value for all three aggregated results unique.

Case 3 - Aggregation other than min() or max() is identified: In such a case, the possible actual aggregations on $f_o$ are $\sum(\text{DISTINCT } f_o)$, $\text{avg}(\text{DISTINCT } f_o)$, $\text{count}(\text{DISTINCT } f_o)$ or the one identified without distinct. In such a case, we generate databases to prune out this list one by one. For example, let us say that $\sum (f_o)$ is the identified projection. To prune out one of $\sum(f_o)$ and $\sum(\text{DISTINCT } f_o)$, we generate a $D_{\text{gen}}$ instance with $k = 2$ and $o_1 \neq 0$. Similarly, other candidates can be pruned out as well. Note that in case of equivalent aggregations, anyone can be chosen.

Extension to non-Numeric Columns

In case of non-numeric column $A$, we need to find existence of min() or max() only. In such a case, we take $k = 1$ and take two different values $a$ and $b$ from the domain of $A$ such that the corresponding output column function returns two different values. The rest of the procedure remains same.

4.3 Order By

We now move on to identifying the sequence of columns present in $\rightarrow O_E$. A basic difficulty here is that the result of a query can be in a particular order either due to: (i) explicit ORDER BY clause in the query or (ii) a particular plan choice (e.g. Index-based access or Sort-Merge join). Given our black-box environment, it is fundamentally infeasible to differentiate the two cases. However, even if there are extraneous orderings arising from the plan, the query semantics will not be altered, and so we allow them to remain.

Here, we expect that each database column occurs in the dependency list of at most one output column. Further, for simplicity, we assume that $\text{count}() \notin A_E$ and that no aggregated output column is a constant function – the procedure to handle these special cases is described at last.

Order Extraction

We start with a candidate list comprised of the output columns in $P_E \cup A_E$. From this list, the columns in $\rightarrow O_E$ are extracted sequentially, starting from the leftmost index. The process stops when either (i) all candidates have been included, or (ii) all functionally-independent attributes
of $G_E$ have been included in $\rightarrow O_E$, or (iii) no sort order can be identified for the current index position.

To check for the existence of an output column $O$, we create a pair of 2-row database instances – $D^2_{same}$ and $D^2_{rev}$. In the former, the sort-order of $O$ is the same as that of all the other output columns, whereas in the latter, the sort-order of $O$ alone is reversed with respect to the other output columns. An example instance of this database pair is shown for the revenue UDF in Figure 4.4.

We use the following procedure to create $D^2_{same}$: Firstly, we divide the output columns into three sets. $S_1$, which represents the output columns that are already present in $\rightarrow O_E$ (initially, $S_1 = \emptyset$). $S_2$, which is a singleton set containing the output column that is currently being analyzed. $S_3$ is the set of all remaining output columns. Let $f_o$ denote the function identified in Section 3.5 for output column $O$. For each $O \in S_1$, we select a single value for the argument columns which feature in $f_o$. For each $O \in S_2 \cup S_3$, we select a pair of argument columns such that both the pair return different values for the output column. All these values are generated keeping the filter and join restrictions in consideration. The data generation for all the tables is as follows: (i) Each column that features in $S_1$ is assigned the single identified value in both the
rows. (ii) Each column that features in $S_2$ and $S_3$ is assigned the pair of identified values in the two rows so that each output column is sorted in the same order. (iv) For all other columns, two values $r$ and $s$ are assigned such that $r < s$ and both $r$ and $s$ satisfy the associated filter predicate (if any). The key attributes which are connected, get same $r$ and $s$ values. Further, in case of equality filter predicate, we take $r = s$.

The procedure for creating $D^2_{rev}$ is the same as above except that the attributes corresponding to the output column in $S_2$ are assigned values in the reverse order to that in $D^2_{same}$.

Database construction in the above manner ensures both the rows form individual groups, so aggregated columns can be effectively treated as projections (except for $count()$, which requires a different mechanism, explained at last). After generating $D^2_{same}$ and $D^2_{rev}$, we run $\mathcal{F}$ for both the instances and analyze the results. If the values in $O$ are sorted in the same order for both the results, $O$ along with its associated order, is added to $\overrightarrow{OE}$ at position $i$, and the sets $S_1, S_2$ and $S_3$ are recalculated for the next iteration.

**Lemma 4.1:** With the above procedure, if $O$ is not the rightful column at position $i$ in $\overrightarrow{OE}$, and another column $O'$ is actually the correct choice, then the values in $O$ will not be sorted in the same order in the two results.

**Proof:** Firstly, as each column in the existing identified $\overrightarrow{OE}$ is assigned the same value in both the rows, they have no effect on the ordering induced by other attributes. Now, let us say that the next attribute in $\overrightarrow{OE}$ is $O'$ (asc) but UNMASQUE extracts $O$. Now in the result corresponding to $D^2_{same}$, the values in $O$ will also be sorted in ascending order. But in the result corresponding to $D^2_{rev}$, the values in $O$ will be sorted in descending order (due to ascending order on $O'$), a contradiction.

With the above procedure, we finally obtain for Q3:

$\overrightarrow{OE} = \{\text{revenue desc, o\_orderdate asc}\}$

**Extension1:** $count(*) \in A_E$

In the case when $count(*) \in A_E$, the two rows in each of the tables is not enough as the count() value for both the groups will be one. In such case, we need an intermediate result (on which grouping will be applied) with 3 rows such that two rows form one group and the third row forms another group. Also, the values in the rows should be according to the order desired after grouping of the intermediate result. So the data generation process is as follows:

To generate data for $D^2_{rev}$, we first choose a table $t$ with at least one attribute in $\text{group by}$
clause that can take two different values and is not present as an argument to any column in $S_1$. For each output column function $f_o \in S_1$, we take argument value $(a_1, \ldots, a_n)$ and assign same values in both the rows to corresponding columns in the table. For each output column function $f_o \notin S_1$, we take two different argument values $(a_1, \ldots, a_n)$ and $(b_1, \ldots, b_n)$ and assign values to corresponding columns in the table. In case the column is a key column we take fixed values 1 and 2. For all the other columns of other tables $t'$, we generate two rows with each attribute having two different values ($p$ and $q$) such that $p < q$. In case of key attributes, take $p = 1$ and $q = 2$. In other cases, take $p$ and $q$ satisfying the corresponding filter predicates (if any). Note that in the above procedure, if we encounter an attribute with equality filter predicate, we take $p = q = val$ where $val$ satisfies the corresponding filter predicate.

Data generation for $D_{\text{same}}^2$ is similar as for $D_{\text{rev}}^2$ with the only change being the values of $p$ and $q$ are now swapped. The further procedure of running $\mathcal{F}$ and analyzing the results is the same as explained in order extraction part of the section. A sample $D_{\text{same}}^2$ and $D_{\text{rev}}^2$ database instance for a hypothetical scenario where revenue is replaced by count(*) is shown in Figure 4.5.

Figure 4.5: $D_{\text{same}}^2$ and $D_{\text{rev}}^2$ for Ordering on count(*) (Hypothetical scenario:Q3)
Lastly, in case \( \text{count(DISTINCT } t.A) \in A_E \), the data generation process is the similar with the change that \( A \) is assigned values \((p, q, p)\) in both the cases.

**Extension2:** \( t.A : \{"t.A = \text{\textquotesingle\textquotesingle}val\text{\textquotesingle\textquotesingle} \in F_E \land (\text{agg\_func}(t.A) \in A_E)\} \)

In case there is \( \text{min()}, \text{max()} \) or \( \text{avg()} \) aggregation on \( A \), the attribute can be treated as natively projected attribute because each group in the output will have exactly the same value for \( A \). Now, if \( \text{sum}(t.A) \in A_E \), the data generation process is same as in Extension 1. Also note that, the aggregation case with \text{DISTINCT} keyword is equivalent to non-aggregated projection.

A closing note on the potential for spurious columns appearing in \( G_E \) due to plan-induced ordering: Since \( D^2_{\text{same}} \) and \( D^2_{\text{rev}} \) are extremely small in size, it is unlikely that the database engine will choose a plan with sort-based operators – for instance, it would be reasonable to expect a sequential scan rather than index access, and nested-loops join rather than sort-merge. In our experiments, we explicitly verified that this was indeed the case.

### 4.4 Limit

If the query is an SPJA query, there is no need to extract \( l_E \) since there can be only one row in any populated result. But in the general SPJGAOL case, the only way to extract \( l_E \) is to generate a database instance such that \( \mathcal{F} \) produces more than \( l_E \) rows in the result \( R \), subject to a maximum limit imposed by the \text{GROUP BY} clause.

The number of different values a column can legitimately take is a function of multiple parameters – data type, filter predicates, database engine, hardware platform, etc. Let \( n_1, n_2, n_3, \ldots \) be the number of different values, after applying domain and filter restrictions, that the functionally-independent attributes \( A_1, A_2, A_3, \ldots \) in \( G_E \) can respectively take. This means that there can be a maximum of \( n_1 \times n_2 \times n_3 \times \ldots = l_E^{\text{max}} \) groups in the result. Thus, \( l_E \) values up to \( l_E^{\text{max}} \) can be extracted with this approach.

To extract \( l_E \), UNMASQUE iteratively generates database instances such that the result-cardinality follows a geometric progression starting with \( a \) rows and having common ratio \( r(> 1) \). We set \( a = \max(4, \text{cardinality of } R) \) to be consistent with our extraction requirement for \( G_E \) which required a permissible result cardinality of upto 3 rows. And \( r \) can be set to a convenient value that provides a good tradeoff between the number of iterations (which will be high with small \( r \)) and the setup cost of each iteration (which will be high with large \( r \)). In our experiments, \( r = 10 \) was used. This appears reasonable given that the \( l_E \) value is typically a small number in most applications – for instance, in TPC-H, the maximum is 100, and in general, we do not expect the value to be more than a few hundreds at most.
Generating $D_{\text{gen}}$ for desired $R$ cardinality

To get $n$ rows in the result prior to the limit kicking in, we generate a database instance with each table having $n$ rows such that the functionally-independent attributes in $G_E$ have a unique permutation of values in each row. Specifically, all the attributes appearing in $JG_E$ are assigned values $(1, 2, 3, \ldots, n)$ and the other attributes are assigned any value satisfying their filter predicates (if any). If the result of applying $F$ on this database contains $m$ rows with $m < n$, then we can conclude that LIMIT is in operation and equal to $m$. With the above procedure, we finally obtain $l_E = 10$ for Q3.
Chapter 5

Experimental Evaluation

Having described the functioning of the UNMASQUE tool, we now move on to empirically evaluating its efficacy and its efficiency. All the experiments were hosted on a well-provisioned PostgreSQL 11 [20] database platform.

5.1 Hidden SQL Queries

Our first set of experiments was conducted on a representative suite of hidden SPJGAOL queries based on different template queries of the TPC-H benchmark, with the primary change being the removal of nesting; and are similar in complexity to the Q3 running example. For convenience, we hereafter refer to them as $Q_x$, where $x$ is their associated TPC-H query identifier. The exact queries are listed in Appendix A. Each query was passed through a Cpp program that embedded the query in a separate executable. These executables formed the input to UNMASQUE, which has been implemented in Python, and were invoked on the TPC-H database, assuring a populated result. UNMASQUE’s ability to non-invasively extract these queries was assessed on a 100 GB version of the TPC-H benchmark, and to profile its scaling capacity, also on a 1 TB environment.

we have also run UNMASQUE on (i) the TPC-DS [26] benchmark with PostgreSQL, and (ii) the TPC-H benchmark with SQL Shield encrypted queries on Microsoft SQL Server [19]. The performance results were of a similar nature.

5.1.1 Correctness

We compared the $Q_E$ output by UNMASQUE on the above $Q_H$ suite with the original queries. Specifically, we verified, both manually and empirically with the automated Checker component

---

1Intel Xeon 2.3 GHz CPU, 32GB RAM, 3TB Disk, Ubuntu Linux
of the pipeline, that the extracted queries were semantically identical to their hidden sources.

5.1.2 Efficiency

The total end-to-end time taken to extract each of the twelve queries on the 100 GB TPC-H database instance is shown in the bar-chart of Figure 5.1. In addition, the breakup of the primary pipeline contributors to the total time is also shown in the figure.

We first observe that the extraction times are practical for offline analysis environments, with all extractions being completed within 40 minutes. Secondly, there is a wide variation in the extraction times, ranging from 4 minutes (e.g. Q2) to almost 40 minutes (e.g. Q5). The reason is the presence or absence of the lineitem table in the query – this table is enormous in size (around 0.6 billion rows), occupying about 80% of the database footprint, and therefore inherently incurring heavy processing costs.

Drilling down into the performance profile, we find that the MINIMIZER module of the pipeline (blue color), take up the lion’s share of the extraction time, the remaining modules (red color) collectively completing within a few seconds. For instance, for Q5 which consumed around 37.2 minutes overall, the MINIMIZER expended around 37 minutes, and only a paltry 12 seconds was taken by all other modules combined.

The extreme skew is because these two modules operate on the original large database, whereas, as described in Chapters 3 and 4, the remaining modules work on miniscule mutations or synthetic constructions that contain just a handful of rows. Interestingly, although the executable $F$ was invoked a few hundred times during the operation of these modules, the execution times in these invocations was negligible due to the tiny database sizes.
5.1.3 Optimization

We now go on to show how MINIMIZATION – could be substantially improved with regard to its efficiency.

Instead of executing MINIMIZER on the entire original database, sampling methods that are natively available in most database systems could be leveraged as a pre-processor to quickly reduce the initial size. Specifically, we iteratively sample the large-sized tables, one-by-one in decreasing size order, until a populated result is obtained. The sampling is done using the following SQL construct:

```sql
select * from table where random() < 0.5;
```
which creates a random sample that is 50% percent relative to the original table size. An interesting optimization problem arises here – if the sample size is set too low, the sampling may require several failed iterations before producing a populated result. On the other hand, if the sample size is set too large, unnecessary overheads are incurred even if the sampling is successful on the first attempt.

Currently, we have found a heuristic setting of Sample Size = 2% in terms of number of rows to consistently achieve both fast convergence (within two iterations) and low overheads. In our future work, we intend to theoretically investigate the optimal tuning of the sample size parameter.

The revised total execution times after incorporating the above two optimizations, are shown in Figure 5.2, along with the module-wise breakups. We see here that all the queries are now successfully identified in less than 10 minutes, substantially lower as compared to Figure 5.1. Further, the FROM clause takes virtually no time, as expected, and is therefore included in the Other Modules category (green color). And in the MINIMIZER, the preprocessing effort spent on sampling (maroon color) takes the majority of the time, but greatly speeds up the subsequent recursive partitioning (pink color).

An alternative testimonial to UNMASQUE’s efficiency is obtained when we compare the total extraction times with their corresponding query response times. For all the queries in our workload, this ratio was less than 1.5. As a case in point, a single execution of Q5 on the 100GB database took around 6.7 minutes, shown by the red dashed line in Figure 5.2, while the extraction time was just under 10 minutes.

Finally, as an aside, it may be surmised that popular database subsetting tools, such as Jailer [15] or Condenser [24], could be invoked instead of the above sampling-based approach to constructively achieve a populated result. However, this is not really the case due to the following reasons: Firstly, these tools do not scale well to large databases – for instance, Jailer
did not even complete on our 100 GB TPC-H database! Secondly, although they guarantee referential integrity, they cannot guarantee that the subset will adhere to the *filter predicates* – due to the hidden nature of the query. So, even with these tools, a trial-and-error approach would have to be implemented to obtain a populated result.

### 5.1.4 Scaling Profile

To explicitly assess the ability of UNMASQUE to scale to larger databases, we also conducted the same set of extraction experiments on a 1 TB instance of the TPC-H database. The results of these experiments, which included all optimizations, are shown in Figure 5.3. We see here that all extractions were completed in less than 25 minutes each, demonstrating that the growth of overheads is sub-linear in the database size. In fact, a single query execution of $Q_5$ on this database took around 72 minutes, almost 3 times the query extraction time.

### 5.1.5 TPC-DS Results for 100 GB

The bar-chart in Figure 5.4 shows the time taken to extract 7 queries sourced from TPC-DS benchmark (along with their identifier numbers) on a 100 GB database version. The exact queries are listed in Appendix A. We can see that all the queries were extracted within 4 minutes. It may surprise at first that the time taken in this case is lesser than the time for TPC-H queries and also, the variation amongst queries is very less. The reason is that the table sizes in TPC-DS are not that skewed as in TPC-H. So, no table in TPC-DS is as huge as *lineitem* table of TPC-H.
Command | Application | Extracted SQL Complexity | Time
--- | --- | --- | ---
get admin comments | Enki | Project, Join, OrderBy, Limit | 1.2 sec
get admin pages | Enki | Project, OrderBy, Limit | 1 sec
get admin pages id | Enki | Select, Project, Limit | 1 sec
get admin posts | Enki | Project, Join, GroupBy, OrderBy, Limit | 2.5 sec
get admin posts id | Enki | Select, Project, Limit | 1 sec
get admin comments id | Enki | Select, Project, Limit | 1 sec
get admin undo items | Enki | Project, Order by, Limit | 0.5 sec
get latest posts | Enki | Select, Project, Join, Filter, GroupBy, Order By, Limit | 1.5 sec
get user posts | Enki | Select, Project, Join, Filter, Group By, Order By, Limit | 2.5 sec
get latest posts by tag | Enki | Select, Project, Join, Filter, GroupBy, OrderBy, Limit | 2.5 sec
get article for id | Blog | Select, Project, join | 1 sec

Table 5.1: Imperative to SQL Translation
5.2 Hidden Imperative Code

Our second set of experiments evaluated applications hosting imperative code. Here we considered the popular Enki [16] and Blog [21] blogging application, both built with Ruby on Rails, each of which has a variety of commands that enable bloggers to navigate pages, posts and comments. The Enki and Blog servers receive HTTP requests, interact with the database accordingly, and respond the client with an HTML page that contains the data retrieved. Enki uses a total of eight database tables and Blog uses two database tables. We created a synthetic database of 10 MB size which gives non-empty result for each of these commands. Along with UNMASQUE, we used Selenium [18] to send an HTTP request and receive the results in HTML page from which the database results are automatically extracted.

Since native data is not publicly available, we created a synthetic 10MB database that provided populated results for all these commands. We found that for Enki, 14 out of 17 and for Blog 2 out of 2 commands were extracted (except insert, update, etc.). Table 5.1 shows the SQL queries extracted w.r.t. the commands. We have omitted five commands as those were simple table scans. The queries corresponding to remaining three commands did not belong to EQC and only SPJ part was extracted correctly for them. We manually verified that all the commands in table 5.1 were extracted correctly. As a sample instance, consider the “get latest posts by tag” command, a snippet of which is outlined in Figure 5.5a. The corresponding UNMASQUE output is shown in Figure 5.5b, and was produced in just 2.5 seconds.

```python
def find_recent(options = {})
    ...
    include_tags = options.include_tags
    order = 'published_at DESC'
    conditions = ['published_at < ?', Time.zone.now]
    result = Post.tagged_with(include_tags)
    result = result.where(conditions)
    result = result.includes(:tags) if include_tags
    ...
```

```sql
SELECT min(posts.title), min(posts.body), max(posts.published_at),
       count(*), min(tags.name)
FROM posts, comments, taggings, tags
WHERE posts.id = comments.post_id AND taggings.tag_id = tags.id
     AND posts.id = taggings.taggable_id AND taggings.taggable_type = 'Post'
     AND (posts.published_at < cur_timestamp)
GROUP BY comments.post_id
ORDER BY max(posts.published_at) DESC LIMIT 15;
```

Figure 5.5: Imperative to SQL Translation
Chapter 6

Extensions

6.1 Extension to non-integral Key attributes

There are various applications (e.g. Wilos [27]) which use non-integral keys as identifier in the database tables. We assume that the domain of each key attribute contains at least two different values. To handle non-integral keys, the following changes are required:

In Mutation Pipeline, only the join predicate extraction module require changes. In this module, instead of negating the values of the columns in $C_1$ (refer Section 3.3), we choose two different fixed values (say $p$ and $q$) from the domain of the key attribute and assign $p$ to the columns in $C_1$ and $q$ to the columns in $C_2$.

For every module in Generation Pipeline, we again take two different fixed values (say $p$ and $q$) from the domain of the key attribute. Then, all the assignments that use fixed value 1 are replaced with value $p$ and all the the assignments that use fixed value 2 are replaced with value $q$.

6.2 Queries with Having Clause

Thus far, we had deliberately set aside discussion of the HAVING clause. The reason is that this clause is especially difficult to extract, stemming from its close similarity to filter predicates in the WHERE clause – this difficulty has led to it not being considered in the prior QRE literature as well. The good news is that we have been able to devise an extraction technique under a few assumptions, the primary one being that the attribute sets in $F_E$ and $H_E$ are disjoint. However,

\footnote{This assumption holds for all the queries of the TPC-DS benchmark.}
incorporating this approach entails a significant reworking of the UNMASQUE pipeline, as well as modified algorithms for some of the modules. Specifically, the extraction of filter predicates is now delayed to after the GroupBy module, and the implementations of the FilterPredicate and GroupBy modules are altered. In addition to the assumptions in Chapter 2, the SPJGA queries with having clause should satisfy the following conditions.

1. The attributes involved in filter predicate in the Having clause and outside Having clause are disjoint.

2. Each attribute has at most one aggregation in the Having clause predicates.

3. The values in the Having clause predicates do not exceed the bounds of corresponding data type.

Note: Here, the operation on only integral attributes are discussed. However, the queries with textual attributes (and LIKE operator) can also be handled in a similar manner as defined in previous chapters.

6.2.1 From Clause Detection
From Clause detection is performed in the same way as described in section 3.1.

6.2.2 Database Sampling
If the initial database instance is huge, the sampling (as defined in Chapter 5) is applied to reduce its size. Note that, the whole database is not copied, but a new table is created with the sampled rows. Also “not null” constraints are not added in the new table.

6.2.3 Join Graph Detection
Join graph detection is performed in the same way as described in section 3.3. Knowledge of join graph helps reducing the database instance more efficiently. As we can not go with the binary partition argument here, using key relations helps in faster database reduction.

6.2.4 Database Minimization
*Given a database instance \( D \) and an executable \( \mathcal{F} \) producing a populated result on \( D \), derive a reduced database instance \( D_{\text{min}} \) from \( D \) such that removing any row of any table in \( T_E \) results in an empty result. We call such database, a minimal database for the query.*

With this definition of \( D_{\text{min}} \), we can prove the following observations:
Lemma 6.1: For the EQC, the output of SPJ part of the query for the minimal $D_{\text{min}}$ constitutes a single group (as per grouping attributes of the query) and the final output contains only a single row.

The minimization is done in the following manner: Let $t$ be a table in the From clause (the set $T_E$) of the query. Initially, for each attribute in $t$, the frequency of each value is calculated. Let $f_{A,j}$ denote the maximum value of frequency with value $j$ in attribute $A$. In each iteration, the rows corresponding to $f_{A,j}$ are preserved, removing all other rows. If a non-empty output is produced, the preserved rows form the new table content on which frequency values are recalculated and the same procedure is repeated. If an empty output is produced, the same procedure is applied with the value having the next maximum frequency. This procedure is repeated until no further reductions are possible in $t$. Once $t$ is reduced, all the tables connected to it in the join graph are reduced to contain only those rows which satisfy the join condition.

The above procedure is applied to each table in the set $T_E$ repeatedly until the database can not be reduced further. The idea behind the step of preserving a particular value of the attribute is as following: if $A$ is a group by attribute, it will contain a single value in the reduced database instance. Further, we first select the value with the maximum frequency as a heuristic because it selects a relatively large number of rows at a time.

Note that if the query belongs to $EQC^{-H}$, the final database will be a one row database. However, we may get a one row database even if the query belongs to EQC. For now, we assume that the reduced database is not a one row database. We discuss the other case in Section 6.2.10.

6.2.5 Group By Attributes

It is clear by $D_{\text{min}}$ construction that any attribute with two or more different values can not be a part of group by clause as it would have created two different groups in the output. So, in order to get the attributes involved in the group by clause, we check for each attribute in the $D_{\text{min}}$ which have a single value in all the rows. For each such attribute $A$ with value $val_1$, we insert each of the current row in the table again with $A$ value being $val_2$ where $val_2 \neq val_1$. However, $val_2$ may not satisfy the unknown filter on $A$, If any. For this, we do this two times, one with $val_2 = val_1 + 1$ and one with $val_2 = val_1 - 1$. Two output rows in any of the two cases indicate $A$ to be present in the group by clause. A similar argument can be used for textual attributes as well.
### 6.2.6 Having Clause and Filters

First we identify possible filter on each group by column using a similar technique as per in section 3.4. After that, the filters on non-grouping attributes are identified.

For a SPJGA query, filter predicate $a \leq A \leq b$ can be re-written in terms of a having clause condition as $a \leq min(A) \leq max(A) \leq b$. The procedure below identifies filter predicate in terms of having clause conditions. Thus hereonwards, a filter on $A$ refers to a filter in the form of $val_1 \leq agg.func(A) \leq val_2$. To detect the having clause condition on an attribute, we change its values in the table, such that only one row of the output group is affected at a time. However, if a foreign key of the table maps to a key of another table in the join graph and values in the foreign key attribute are not unique, one change in the table will affect multiple places in the output group. So we transform the tables in a way such that all key values in all the tables are unique and there is one-to-one relationship between the tables. This can be done by traversing the join graph and duplicating rows in the table with new key identifiers. For example, let $T_1[(1, “a”, 2), (2, “b”, 2)]$ be a table with two rows and $T_2[(2, “c”)]$ be a table with a single row where last attribute of $T_1$ refers to the first attribute of $T_2$. Then these tables are transformed as $T_1[(1, “a”, 1), (2, “b”, 2)]$ and $T_2[(1, “c”), (2, “c’”)]$. Note that both the joins (before and after transformation) produce same output except the key attribute contents.

Let $[i_1, i_2]$ be the integer range. Let $(a_1, a_2, ..., a_n)$ be the values in attribute $A$ in non-decreasing order. WLOG, let us assume $a_i$ is the value in attribute $A$ in the $i^{th}$ row. For a filter predicate $val_1 \leq A \leq val_2$, Let us call $A \geq val_1$ as the left filter on $A$ and $A \leq val_2$ as the right filter on $A$. We first define the term rowno and val. Starting from 1 to $n$, if we keep decreasing the value of $a_i$ to $i_1$, rowno denotes the first row, in which the values in $A$ can not be decreased to $i_1$ without losing the output. Also, rowno = none if values in all the rows can be decreased to $i_1$. Further, if rowno ≠ none, val denotes the minimum value in row rowno which can be present without losing the output. The following algorithm is used to get rowno and val.

Now, the following two cases arise:

**Case 1:** rowno = none. In this case, there is no left filter condition on $A$. The reason is that, we were able to reduce value in every row to minimum possible value without losing the output.

**Case 2:** rowno ≠ none. If rowno ≠ 1 and rowno ≠ $n$, there is a having clause predicate
Algorithm 3: Getting rowno and val for left filter

```
1 rowno = none, val = none
2 for i in range 1 to n do
3     val ← the minimum value in \([i_1, a_i]\) which gives non-empty result.
4     if val = i_1 then
5         Replace a_i with i_1 in the database
6         val = none continue
7     end
8     Replace a_i with val in the database
9     rowno = i
10    break
11 end
```

on A with either \(\text{sum()} \geq val_1\) or \(\text{avg()} \geq val_1\). The reason is that, if there were a condition \(\min(A) \geq val_1\), the value of rowno should have been 1. Similarly, if here were a condition \(\max(A) \geq val_1\), the value of rowno should have been \(n\). Now, if rowno = 1, the aggregations in the filter predicate may be \(\text{sum}(), \text{avg}()\) or \(\text{min}()\). To differentiate amongst these, we decrease the value in the first row by 1 and increase the value in any other row by 1. This makes sure that the \(\text{sum}(A)\) and \(\text{avg}(A)\) does not change while changing \(\min(A)\). If we get an output, the filter is either \(\text{sum()} \geq val_1\) or \(\text{avg()} \geq val_1\) otherwise it is \(\min(A) \geq val_1\). A similar method can be used to differentiate amongst \(\text{sum}(), \text{avg}()\) or \(\max()\) when rowno = \(n\). The corresponding filter value \(val_1\) will be the \(val\) obtained from the algorithm.

To find the right filter on A, a similar approach can be used with a new definition of rowno and val. Starting from \(n\) to 1, if we keep increasing the value of \(a_i\) to \(i_2\), rowno denotes the first row, in which the values in A can not be increased to \(i_2\) without losing the output. Also, rowno = none if values in all the rows can be increased to \(i_2\). Further, if rowno \(\neq\) none, val denotes the maximum value in row rowno which can be present without losing the output. The following algorithm is applied to get the rowno and val.

After getting rowno and val, right filter can be found in a similar way using the following two cases:

**Case 1:** rowno = none. In this case, there is no right filter condition on A.

**Case 2:** rowno \(\neq\) none. If rowno \(\neq\) 1 and rowno \(\neq\) \(n\), there is a having clause predicate on A with either \(\text{sum()} \leq val_2\) or \(\text{avg()} \leq val_2\). Now, if rowno = \(n\), the aggregations in the
Algorithm 4: Getting rowno and val for right filter

1 \( \text{rowno} = \text{none}, \text{val} = \text{none} \)
2 \textbf{for} i in range n to 1 \textbf{do}
3 \hspace{1em} val ← the maximum value in \([a_i, i_2]\) which gives non-empty result.
4 \hspace{1em} \textbf{if} val = i_2 \textbf{then}
5 \hspace{2em} Replace \(a_i\) with \(i_2\) in the database
6 \hspace{2em} val = none
7 \hspace{2em} continue
8 \hspace{1em} \textbf{end}
9 \hspace{1em} Replace \(a_i\) with \(val\) in the database
10 \hspace{1em} rowno = i
11 \hspace{1em} break
12 \textbf{end}

filter predicate may be \(\text{sum}()\), \(\text{avg}()\) or \(\text{max}()\). To differentiate amongst these, we increase the value in the \(n^{th}\) row by 1 and decrease the value in any other row by 1. This makes sure that the \(\text{sum}(A)\) and \(\text{avg}(A)\) doesn’t change while changing \(\text{max}(A)\). If we get an output, the filter is either \(\text{sum}() \leq \text{val}_2\) or \(\text{avg}() \leq \text{val}_2\) otherwise it is \(\text{max}(A) \leq \text{val}_2\). A similar method can be used to differentiate amongsts \(\text{sum}()\), \(\text{avg}()\) or \(\text{min}()\) when \(\text{rowno} = 1\). The corresponding filter value \(\text{val}_2\) will be the \(\text{val}\) obtained from the algorithm.

Note that we have not yet differentiated between the filters on \(\text{sum}()\) and filters on \(\text{avg}()\). Here we make use of the leverage to have null values in our database. Let the current average of the values in column \(A\) be \(a\). To differentiate between the two for an attribute \(A\), we insert a row in the table such that the column \(A\) is assigned value 0 (if operator is \(\geq\)) or it is assigned value \(a\) (if operator is \(\leq\)) group by attributes get the same value, the other attributes with \(\text{sum}()\) or \(\text{avg}()\) filter are assigned null in the new row and all other attributes get any value satisfying the filter predicate. This construction ensures that the output state is directly dependent on the changes made in attribute \(A\). Based on the output on this new database, we can differentiate between \(\text{sum}(A)\) and \(\text{avg}(A)\). Further if the average is a floating point number, we can refine it using binary search assuming fixed precision.

6.2.7 Having condition with count()

After identifying all other filters, the filter with \(\text{count}()\) can be done in a manner analogous to finding limit in section 4.4.
6.2.8 Projection Clause

The projections are identified in a manner analogous to the method defined in Section 3.5. However, while calculating the function, all the rows of the columns in dependency list are assigned same value and final coefficients are divided by number of rows produced after the join and filters.

6.2.9 Other Clauses

If there is no filter with $count(*)$ in the having clause, we can create a single row database satisfying all the filters. Hence, procedures similar to the ones described for queries in $EQC^{-H}$ can be used. In case of presence of a filter of the form “$count(*) \ op \ k$”, we add an additional constraint of number of rows for each of the other modules.

6.2.10 One Row database for SPJGHA[OL] query

While database minimization, we may get a one row database for a SPJGA query with Having clause as well. However, to detect Having clause properly, we need database such that the intermediate output of SPJ part contains at least two rows. In such a case, we first detect the group by clause as mentioned in Section 6.2.5. After that, in each table, we insert the existing row again with a different key value. If we get a two row output, we can conclude the query is an SPJ query. If we get a single row output, we now have a single group database with more than one row in the intermediate SPJ output. However, we may get an empty output as well. Consider an attribute $A$ containing a value 6 in the database currently. There is a Having clause condition on $A$ defined as $\text{sum}(A) < 10$. In such a case, replicating the value will make $\text{sum}(A) = 12$ and hence we will not get any output. As there is no way of knowing beforehand, which attribute caused output to be non-empty, we place null value in a subset of attributes starting from size 1 subsets until we get a non-empty output.

6.2.11 UDF’s in Projection

In the absence on a Having clause filter of type $val_1 \leq \text{sum()} \leq val_2$, the techniques defined in section 3.5 can be used to detect UDF in the having clause by placing a single unique value in every row of each column. However, in the presence of such filter, we may not be able to do so as we may not have much choice for arbitrary unique values in the column. In such a case, we may get an under-determined system of equations and any solution can be treated as the UDF.
6.3 Discussion on Other Operators

A natural question to ask at this point is whether it appears feasible to extend the scope of our extraction process to a broader range of common SQL constructs – for instance, outer-joins, disjunctions and nested queries. As mentioned previously, none of these constructs are handled by the current set of QRE tools. However, based on some preliminary investigation, it appears that outer-joins and disjunctions could eventually be extracted under some restrictions – for instance, the IN operator can be handled if it is known that the database includes all constants that appear in the clause. Nested queries, however, pose a formidable challenge that perhaps requires novel technology. In this context, an interesting possibility is the potential use of machine-learning techniques for complex extractions.
Chapter 7

Theoretical Results

In this chapter, we prove that for arbitrary queries, Hidden Query Extraction is an undecidable problem. We use the following problem to prove the undecidability of HQE.

**Semantic Equivalence of queries (SE):** Given two arbitrary queries $Q_1$ and $Q_2$, determine if $Q_1$ and $Q_2$ are semantically equivalent.

Semantic equivalence of two arbitrary SQL queries is a well known undecidable problem [1]. Further, we say that $SE(Q_1, Q_2) = true$ if $Q_1$ and $Q_2$ are semantically equivalent, and false otherwise. Before moving on to the main theorem of this chapter, we first state and prove the following lemma.

**Lemma 7.1:** Let $Q_1, Q_2$ be two arbitrary queries. For any query $Q$,

$$(SE(Q_1, Q_2) = true) \implies (SE((Q - Q_1) \cup (Q_1 - Q), (Q - Q_2) \cup (Q_2 - Q)) = true)$$

**Proof:** If Part: Let $SE(Q_1, Q_2) = true$, then for any database instance $D$, $Q_1(D) = Q_2(D) = R$. Further let $Q(D) = R'$. Then,

$$(Q - Q_1) \cup (Q_1 - Q))(D) = (Q(D) - Q_1(D)) \cup (Q_1(D) - Q(D)) = (R' - R) \cup (R - R')$$

and
\[(Q - Q_2) \cup (Q_2 - Q))(D) = (Q(D) - Q_2(D)) \cup (Q_2(D) - Q(D)) = (R' - R) \cup (R - R')\]

Hence, \(SE((Q - Q_1) \cup (Q_1 - Q), (Q - Q_2) \cup (Q_2 - Q)) = true\).

**Only If Part:** Let \(SE(Q_1, Q_2) = false\). It means that there exists a database instance \(D\) such that \(Q_1(D) \neq Q_2(D)\). WLOG, Let \(t\) be a tuple that is present in \(Q_1(D)\) but not in \(Q_2(D)\). Now there are two possible cases:

**(Case 1)** \(t \in Q(D)\): In this case

\[(t \in Q(D) \land t \in Q_1(D) \implies t \notin ((Q(D) - Q_1(D)) \cup (Q_1(D) - Q(D)))\]

and

\[(t \in Q(D) \land t \notin Q_2(D), \implies t \in ((Q(D) - Q_2(D)) \cup (Q_2(D) - Q(D)))\]

Hence, \(SE((Q - Q_1) \cup (Q_1 - Q), (Q - Q_2) \cup (Q_2 - Q)) = false\).

**(Case 2)** \(t \notin Q(D)\): In this case

\[(t \notin Q(D) \land t \in Q_1(D) \implies t \in ((Q(D) - Q_1(D)) \cup (Q_1(D) - Q(D)))\]

and

\[(t \notin Q(D) \land t \notin Q_2(D) \implies t \notin ((Q(D) - Q_2(D)) \cup (Q_2(D) - Q(D)))\]

Hence, \(SE((Q - Q_1) \cup (Q_1 - Q), (Q - Q_2) \cup (Q_2 - Q)) = false\).

Now, we prove that the Hidden Query extraction problem is undecidable in general.
Theorem: For an arbitrary hidden query (denoted as black-box function $F$), Hidden Query Extraction (HQE) problem is Undecidable.

Proof: Suppose that HQE is decidable. Then, there exists a deterministic algorithm $A$ such that for any database instance $D$ and a function $F$ with $F(D) \neq \phi$, $A(F, D)$ produces a $Q_{out}$ which is semantically equivalent to unknown hidden query in $F$. Further, let us say $F_1 = H(Q_1)$ and $F_2 = H(Q_2)$ where $H$ is some function (or a wrapper) which simply hides the query. To continue our proof, we state and prove the following two lemmas first.

**Lemma 7.2:** $Q_1$ and $Q_2$ are semantically equivalent if $F_1 = F_2$.

**Proof:** $F_1$ and $F_2$ can be seen as relations which relate the set of database instances to a set of result instances. If $F_1$ and $F_2$ represent the exact same relation, $Q_1$ and $Q_2$ will be semantically equivalent otherwise there would exist at least one $D$, which is mapped to different results in $F_1$ and $F_2$. Similarly, the other direction can be proved. □

**Lemma 7.3:** For any $F_1$, $F_2$ and $D$, $(F_1 = F_2) \implies (A(F_1, D) = A(F_2, D))$. Also, $(A(F_1, D) = A(F_2, D)) \implies (F_1 = F_2)$.

**Proof:** The first statement holds because $A$ is deterministic algorithm. The second statement can be proved by contradiction. Let us say that $A(F_1, D) = A(F_2, D) = Q$ but $F_1 \neq F_2$. Now, $Q$ will be semantically equivalent to the query in $F_1$ and $F_2$ both while $F_1 \neq F_2$, a contradiction for Lemma 7.1. □

Let $Q_1$, $Q_2$ be two arbitrary queries. **We prove that if HQE is decidable, there exists a deterministic algorithm for $SE(Q_1, Q_2)$ for arbitrary queries $Q_1$ and $Q_2$.** WLOG, let us say that $Q_1$ and $Q_2$ are compatible in set difference ('-') and set union ('∪') operations. If this is not the case, we can say that $Q_1$ and $Q_2$ are not equivalent. Further, let $Q$ be any simple project join query which is compatible with $Q_1$ and $Q_2$ for ‘−’ and ‘∪’ operations. Note that such query $Q$ can be generated easily after observing the result column data types of $Q_1$ or $Q_2$. Also, let $D$ be a database instance such that $Q(D) \neq \phi$. Note that, although finding such $D$ is a hard problem in general, it can be easily done in case of a project join query. We define two black-box functions as follows:

$$F_1 = H((Q - Q_1) \cup (Q_1 - Q))$$

and
\[ F_2 = H((Q - Q_2) \cup (Q_2 - Q)) \]

WLOG, let us say that \( D \) gives same non-empty result on \( F_1 \) and \( F_2 \). Note that if this is not the case, then by Lemma 7.1, \( Q_1 \) and \( Q_2 \) are not semantically equivalent. Further, if \( D \) gives empty result in both cases, it means that \( D \) gives a non-empty result on \( Q_1 \) and \( Q_2 \). In such a case, we take \( F_1 = Q_1 \) and \( F_2 = Q_2 \) and keep the \( D \) as it is. Now that we have \( F_1, F_2 \) and \( D \), using Lemma 7.2 and Lemma 7.3, we can say that

\[
(A(F_1, D) = A(F_2, D)) \implies (F_1 = F_2) \implies SE(Q_1, Q_2)
\]

Thus, presence of a deterministic algorithm for HQE shows the presence of a deterministic algorithm for \( SE \). As \( SE \) is known to be undecidable, so is HQE.
Chapter 8

Conclusion and Future Work

We introduced and investigated the problem of Hidden Query Extraction as a novel version of QRE, which has a variety of real-world use-cases. As the first step toward solving this problem, we presented the UNMASQUE algorithm, which is based on a combination of database mutation and database generation pipelines. An attractive feature of UNMASQUE is that it is completely non-invasive, facilitating its deployment in a platform-independent manner.

UNMASQUE is capable of identifying a large class of hidden SPJGHAOL queries, similar to those present in the decision-support benchmarks. Potent optimizations related to database minimization and order detection were incorporated to reduce the overheads of the extraction process. Specifically, for the most part, the extraction pipeline works on miniscule databases designed to contain only a handful of rows. The effects of these optimizations were visible in our experimental results which demonstrated that query extraction could be completed in times comparable with normal query response times in spite of a large number of executable invocations.

In our current work, we are attempting to extend the scope of EQC to include the Having clause in a more general sense. Also, a mathematical analysis to help choose the appropriate SZ setting for sampling. For the long-term, the extraction of nested queries and outer joins poses a formidable challenge. More fundamentally, characterizing the extractive power of non-invasive techniques is an open theoretical problem.
